

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. DIVISION OF STRICTURES

H. DICK.

ON THE
CUTANEOUS AND OTHER METHODS

OF

FIXING STRICTURES OF THE
URETHRA.

BY

HENRY DICK, B.A., M.D.,

LATE SURGEON TO THE NATIONAL ORTHOPÆDIC HOSPITAL.
AUTHOR OF A WORK ON 'GLEET, ITS PATHOLOGY AND TREATMENT.'

~~~~~  
With Twenty-one Woodcuts.  
~~~~~

LONDON:
HARDWICKE AND BOGUE, 192, PICCADILLY, W.
1878.

160. e. 184.

INTRODUCTION.

SINCE my paper was read before the Medical Society of London and published in the 'Medical Press and Circular' (Jan. 17th, 1877), I have had numerous letters and applications concerning the different instruments—exhibited to the Society—used by me in treating strictures. Others have asked me (principally from America) about the mode of performing the subcutaneous operation.

These inquiries have induced me to publish the paper with woodcuts; and, in addition, the paper I read before the Royal Medical and Chirurgical Society of London in the year 1864, together with the case given in illustration, operated upon successfully by my friend, Mr. William Adams. The subcutaneous section of strictures *if not properly executed and also rationally treated* afterwards will not succeed. It has the great advantage over the other operative proceedings for the cure of strictures, that it can, by its application and *proper after-treatment*, better fulfill the surgical indica-

tions for curing strictures. Contraction, deviation of the urethra, and also fistula, and retention of urine are the practical points I have in mind in publishing the two papers. But I advise the practical surgeon to pay great attention to the above-mentioned points in the pathological anatomy, and if his treatment is in accordance with the principles I have pointed out, he will not be so often disappointed in the treatment, as we daily see in many cases of strictures operated upon by other methods.

HENRY DICK.

THE
SUBCUTANEOUS AND OTHER METHODS
OF
DIVIDING STRICTURES OF THE URETHRA.*

FROM the title of my paper do not expect a long introduction on the pathology of strictures of the urethra, or the description of the different forms and their treatment. I will only touch upon the practical points and controversies of cutting strictures. Days and weeks would not be sufficient to discuss the actual state of the surgery of urethral stricture, and this meeting of a few hours' duration can only be usefully occupied in discussing the operation of cutting strictures, and what is, in my opinion, the best method of cutting them.

Do not believe, when I speak of operations upon strictures, that I am a great partisan of cutting them. I have stated years ago in all my writings, that division of strictures should be in most cases the exceptional treatment. The best

* Read before the Medical Society of London, Nov. 20, 1876.

6 ON THE SUBCUTANEOUS AND OTHER METHODS

and safest treatment, according to my experience, is the methodical and gradual dilatation by the metallic urethral bougie (see Plate I., Fig. 1); each metallic bougie remaining about five minutes, and passing, as the case may be, one or two, or even three to four sizes at one visit; of course, with caution to avoid accidents, such as orchitis, which, in cases where the stricture is near the prostate gland, and is in an irritable state, or very contracted, the bougie is liable to produce. I use the expression metallic urethral bougie, because such bougie should imitate the anatomical shape of the urethra. In all our books very little difference is made between the urethral bougie and the bougie used for other purposes in disease of the bladder and prostate gland. Its length should be so constructed that it does not go beyond the urethra and enter into the bladder.

The practice of gradual dilatation has been very successful in my hands during the last thirty years. About ten years ago I observed that to leave the metallic bougie only a short time in the urethra was more advantageous than to leave it a long time, or even twenty-four hours, as some surgeons still recommend.

At the same time I take the liberty to exhibit here my improved metallic explorator of the urethra (see Plate I., Fig. 2), which has many

advantages over the old elastic *bougie à boule*. In practice the *bougie à boule* and the *bougie olivaire* have been often confounded. I dare say you have read the controversy about it in the 'Lancet,' so I will not say more on this subject. In my metallic explorator you observe the shoulder is rather abrupt, and the reason of this is, because in drawing back, deviation or slight tightening in the urethra can be detected.

For the diagnosis of strictures near the orifice of the urethra, or any other disease near the orifice of the urethra I use this speculum (see Plate II., Fig. 3 and c) I now exhibit to the Society. But to come back to my subject of cutting strictures of the urethra, I am obliged to state that in some exceptional cases dilatation will not succeed.

Some patients will object to the long treatment by the metallic bougie; or they are on active service in the colonies, and have no time to stay in England; they want to be cured, and avoid the risk of being troubled with retention of urine in a distant country where good medical advice is scarce. Or in some cases the stricture or strictures are so contracted, that dilatation is almost impossible, or, if even dilated, the strictures remain open only for a very short time, and retention of urine recurs at the slightest cold or a little excess in *Baccho et Venere*. In all such cases I think

division of the stricture is required. Other methods of treatment have been recommended for such cases, as splitting, *potassa fusa*, electric cauterization.

I shall give briefly my personal experience and view of these methods of treatment. Splitting was introduced into English surgical practice about fifteen years since, and has found many advocates. At that period nobody knows better than you, Sir, that I prophesied, "The profession will be disappointed." The prophecy has been realized. The reasons I then gave were (1) we do not tear parts in surgery when they can be cut; (2) we do not know what we tear; and (3) the constitutional disturbance and subsequent local contraction after lacerated wounds is more severe than after incised wounds; (4) the local nervous system of the urethra will certainly be more injured, and therefore the patient will be more exposed to pyæmia. I know one case where the operation of splitting the stricture could not be performed, because the toughness of the pathologically composing parts of the stricture resisted all efforts of the splitting instrument.

I oppose cauterization of strictures on several grounds: (1) There is nothing to be destroyed; the constriction of the urethra is the result of want of material; it is contraction; (2) if we destroy

the contraction by *potassa fusa*, or the electric cautery, we shall have a new cicatricial tissue more troublesome than the previous stricture. We see the result of burning in cicatrices on the external surface of the human body, and how troublesome they are to treat. We do not burn again cicatrices after burns, but we divide them; or, in some cases, try the mechanical treatment of extension. Cauterized strictures seen four or five years after the operation, have been the most troublesome in my practice.

Having stated my objection to splitting and cauterizing strictures, I will now give my views on cutting them.

Several methods of cutting have been proposed and practised: (1), Internal Division; (2), External Division, which is practised by different methods, (a) Syme's operation; (b) *la boutonnière*; and (c) my operation, the subcutaneous division of strictures. I call it my operation, because efforts have been made *to deprive* me of the credit of the invention of this method of operating. Before I had published my first case in the 'Medical Times and Gazette,' 1853, there was not one word mentioned in any book or in any printed matter previous to this date on the subcutaneous division of strictures. It has been attributed to two dead men to have performed this operation, by a

surgeon who wrote a book in the year 1869 on the subject of stricture. Unfortunately for the writer I have the clearest proof of his error, not to call it by a more severe expression.

In the year 1853, Mr. Syme read a paper on his operation before the Royal Medical and Chirurgical Society of London, and I wrote the review on it in the 'Medical Times and Gazette,' and in this review I have related a case of my operation in contrast with Syme's operation. Syme never laid any claim to the operation at that period. Mr. Avery never laid any claim to the operation. There is still a member of our profession alive who will testify to the accuracy of my assertion, and who was present at my conversation with the late Mr. Avery on the subject. I could give you further proofs of my assertion, but I will not detain you longer on the subject by my personal complaints against the erroneous writings by surgeons on this subject.

The most frequently practised operation in our time is the internal division of strictures, and a number of instruments have been invented to make the operation safe and successful.

I have given up the operation for these reasons:—(1) We have to confide too much to mechanism in cutting strictures, and the tyro surgeon will find great difficulty in using them;

they will be even dangerous in his hands if not used with the greatest precaution. (2) We are never sure we are cutting in the exact spot, or have cut completely the whole extent of the stricture. I know many contrivances have been made to obviate the uncertainty of the above-mentioned instruments. In theory they seem correct, but in practice they prove faulty. With the internal urethrotome we cannot be sure we have made a *deep* and long cut; nor can we be sure that the stricture is completely divided, and without these precautions a certain failure will be the result of the operation. If the first cut of the urethrotome is a failure, the instrument cannot be introduced with ease in the same sitting. I practise internal division only in cases of strictures near the orifice of the urethra, which is done by a grooved dilator (I now exhibit here, see Plate II., Fig. 4) and a small tenotome (see Plate II., Fig. 5). The grooved and conducting dilator (see Plate II., Fig. 4) is a modification of the instrument of the late M. Reybard, of Lyons. M. Reybard is quite correct in believing that to cut a stricture with success it should be stretched; but this only can be done with certainty in strictures in the neighbourhood of the orifice of the urethra. I have found in practice, that in deep-seated strictures in opening the two blades of the dilator the

instrument gets displaced, and we are not sure then that we are stretching and cutting on the most contracted spot. That is the reason I have omitted to arm my conducting instrument for cutting strictures subcutaneously deep down in the urethra with any dilating blades. In one case, where I had the advantage to have the able assistance of your President last year, he could convince himself of the easy execution of the operation.* I also exhibit here an instrument which I leave in the urethra after the operation to arrest hæmorrhage, and which I call *Sonde-tourniquet* (see Plate III., Fig. 7). I also exhibit to the

* In October, 1877, I was requested to see a patient at the National Hospital for the Paralysed and Epileptic in Queen's Square, C. N., æt. 35, suffering from incomplete retention of urine caused by stricture about two inches from the orifice, and also an extremely contracted condition of the orifice of the urethra, through which a catheter only of the smallest size could be with difficulty introduced.

As this seemed to be a favourable case for Dr. Dick's operation, which I had seen him successfully perform on several occasions, I requested him to see the patient with me, and as he concurred in the opinion I performed the operation with his assistance. At first I introduced the conducting dilator, and after opening the two blades, divided the contracted orifice by introducing Dr. Dick's broad-bladed knife. The deeper stricture, about two inches from the orifice, was then detected, and, after carrying forward the conducting dilator, I divided this by introducing an ordinary tenotomy knife through the urethral orifice. After this, I easily introduced a metallic bougie of the size of No. 10, English gauge. Very little bleeding occurred, and no unfavourable symptoms or urethral fever followed. He was greatly relieved, and able to pass his water freely some weeks before he left the hospital. In this case it seemed to me that Dr. Dick's operation was a great improvement upon the other methods ordinarily in use.

WM. ADAMS.

Society the knife (see Plate II., Fig. 5) I use in the operation of the retracted orifice of the urethra, and the shape of the small metallic bougie is represented in Plate II., Fig. 6, used for preventing the closing of the orifice after operation. I will state here that I use for the division of strictures one inch or two inches from the orifice of the urethra a tenetome, which is introduced through the orifice; but for incision of the contracted orifice I use this knife (see Plate II., Fig. 5). After many trials of other methods for incising the retracted orifice of the urethra, I have found this shape of knife, with the grooved dilating conductor, the most successful method for incising the contracted orifice.

External division may be performed by three methods :—

(a) Syme's operation, which is an operation almost as severe as cutting for stone.

In Syme's operation, strictures are divided which have no connection with the strictured part. The wound is large, the healing process is long, consequently more danger of pyæmia; and after such a large wound, recontraction of the divided parts is more to be feared. The only exceptional indication for Syme's operation may be traumatic strictures, where sometimes the skin does contribute to the contracted stricture or strictures; but even in

these cases I would give first a trial to the harmless subcutaneous division, and try to overcome the skin cicatrices by dilatation; or the contracted cicatrices of the skin in some cases I would treat after Mr. William Adams's method,* or by rhinoplastic operations. I should proceed to Syme's operation only after the failure of the subcutaneous method.

(b) The *boutonnière* is another mode of operating on impassable strictures; it is also external division of the urethral stricture.

I was at one time a great partisan of *la boutonnière* when no instrument can be passed. But I must say that I am very sceptical about such strictures where no instrument can be passed. The resources of surgery thirty years ago were limited, but since we have the whalebone *olivaire bougie*, since we have the *bougie entortillée*, I think that with patience very few strictures are impassable, and once the smallest bougie passed, even of the size of a hair, the retention of urine ceases, according to my experience. Impassable strictures are generally in a state of swelling and inflammation, and it is this and the tortuous nature of the stricture which make them impassable. The retention of urine increases the

* "On a New Operation for the Obliteration of Depressed Cicatrices after Glandular Abscesses and Exfoliation of Bone," by W. Adams, F.R.C.S., 'Brit. Med. Journal,' p. 260, 1875.

inflammation of strictures, and as soon as the bladder is relieved, the stricture becomes amenable to treatment. If all efforts to pass the finest bougie fail, there remains, as the last resource, the subcutaneous puncture of the bladder in connection with the vacuum pump, an operation without danger and of easy execution. After having stated my convictions on this subject, I believe the cases where *la boutonnière* is indicated have greatly diminished.

(c) I will now speak, lastly, of the subcutaneous operation for curing strictures.

I have practised this operation in cases in which it is indicated during the last twenty-five years. The operation is of easy execution. I have described it in another place,* and I will not repeat its mode of performance. I will only show you the instruments I use for the performance of the operation. (1) A grooved conductor† (see Plate IV., Fig. 11, A and B). (2) A tenotome (see Plate II., Fig. 5) for cutting strictures subcutaneously in front of the scrotum, and this long-necked tenotome (see Plate III., Fig. 9) for strictures behind the scrotum.

Some surgeons have expressed the opinion,

* 'Proceedings of the Royal Medical and Chirurgical Society of London,' vol. iv., 1864, p. 361.

† I have seen my conductor altered by diminishing the size of the knobs. This is an error. The knobs should be prominent to be good guides for the finger; and, secondly, to stop at the *widest* part of the stricture, and act also as a stretcher to the stricture.

that the subcutaneous division of strictures is only useful in cases of strictures of the penal portion of the urethra, or in single strictures. This is an error. The subcutaneous division of strictures is practicable in all portions of the urethra, and for all kinds of strictures. In fact, I have found it easier to divide strictures subcutaneously in the membranous portion than in any other part of the urethra, because the finger of the left hand, when introduced into the rectum, can easily feel the long-necked tenotome and the knobs of the grooved conductor.

Two causes of failure in treating strictures by division have frequently been overlooked in practice, namely, (1) incomplete division of strictures; and (2) the faulty after-treatment. But complete division of stricture is so essential to the success of the treatment that, when neglected, the after-treatment cannot remedy it. That is the reason surgeons are so often disappointed with the result of the operation. Therefore, the general opinion of surgeons is a disbelief in any successful treatment of strictures. In my own practice I had several examples illustrating the difficulties to be overcome.

You remember, Sir, the case of the gentleman in St. John's Wood, where I had the advantage of your assistance, where, after the first cut, the

bougie à boule indicated a small obstacle farther down, and I found it prudent, with your assent, to plunge the tenotome through the farther obstacle. The result of the operation, which was a complete success, has proved the truth of this principle. It is now three years since the operation was performed, and the urethra of the patient has remained in a healthy state.

In a later case, where, Sir, you were present too, I repeated the operation three weeks after the first operation, because in the meantime I had convinced myself that another obstacle existed farther down the urethra, and without cutting this obstacle the operation would have been a failure. After the second operation the treatment was successful.

I have seen one of my cases about six months ago, operated upon fifteen years since. The gentleman is married and has one child. In this case I could not find the least trace of a stricture. I think, Sir, you will also remember a case I sent to you for examination, operated upon about six years before, and you could not detect a vestige of stricture.

I think I must attribute the success of my operation to three causes :—1. By the subcutaneous method the stricture can always be divided in its entire length and depth. 2. During the

treatment I pass an instrument, which I call *bougie à bulbe* (see Plate III., Fig. 10), and I now exhibit it to you. By this instrument the portion of the urethra operated upon is made much larger than the rest of the urethra, and so allows some room for contraction of the cicatrix when this takes place. The third precaution is (when the stricture is divided) to dilate the stricture several times a week in the first six months after the operation. According to my experience contraction is to be most feared during the first six months, and the liability to it is kept up during the first two years after the operation. A well-known surgeon said once in his lectures on the treatment of strictures, "Do what you will, tear them, cut them, dilate them, the stricture will return again." Well, that is a sad prospect for surgery! I am not of the same opinion. When I saw in my earlier practice strictures operated upon turn out unsatisfactorily, or being a complete failure, or even worse than before the operation, many reflections took place in my mind. I asked, what is the reason of these failures? Why do they contract again; some later, some as early as three months after the operation? We see these relapses in other operations, principally in orthopædic surgery, such as club-foot, contracted hand, &c. What is the reason of a relapse after the opera-

tion? There are two reasons for relapse after operation in orthopædic surgery; one is that not all parts constituting the deformity have been divided; the second is, that the after-treatment has not been properly conducted, or continued long enough.

I believe a stricture well operated on, well treated afterwards, and carefully attended, will not recontract. Wounds of tendons, or any tissue, will contract, when neglected; we see such cases daily in the cure of clubfoot. In fact, at this moment, many surgeons of our day are very sceptical about the cure of club-foot by operation, repeating the same story as of strictures. Those cases have been simply either neglected or badly operated on. The plain truth is, we can cure a club-foot in modern times. From what I have now stated, I come to the following conclusions:—

1. A stricture can be cured by dividing it.
2. That the easiest and surest method is the subcutaneous incision, with few exceptions, in which other operations are indicated.
3. The cut should always be long and deep.
4. That two years' treatment is necessary to ensure a successful result.

MR. ADAMS'S CASE.

Extracted from the 'Proceedings of the Royal Medical and Chirurgical Society of London,' vol. iv., No. VI., p. 364. 1864.

In June, 1862, C. W., æt. 26, an officer in the army, first consulted Mr. Adams on account of a very severe stricture of the annular or ring-like form and gristly substance situated in the anterior portion of the urethra, two inches and a quarter from the external orifice. The stricture, which could easily be felt by external examination, had been caused by the bite of a horse in India a year and a half previously, and the inconvenience now suffered by the patient incapacitated him for military duty. At the time of the accident both the scrotum and penis were much injured; profuse hæmorrhage from the urethra occurred, and a portion of the mucous membrane is said to have protruded from the external orifice. Abscess formed and opened externally close to the frænum, where a fistulous opening communicating with the urethra remained at the date of Mr. Adams's operation. Ever since his recovery from the immediate effects of the injury, the patient had been obliged to wear, night and day, a short catheter of small

calibre (about No. 2); the disposition to contraction being so great that if this were discontinued more than a few hours, he had the greatest difficulty in passing a tube even of less diameter than a No. 1 catheter. Mr. Adams considered that an operation offered the only means of permanent cure; but at the patient's request this was postponed, and gradual dilatation tried by a graduated series of short silver catheters. The patient left town, and persevered in this treatment for eight months, wearing a catheter day and night. Dilatation could not be carried further than to admit a No. 4 catheter, which was habitually worn, when Mr. Adams was again consulted in February, 1863. The disposition to contraction was so great that when the No. 4 catheter was left out during the night, only a No. 1 or No. 2 catheter could be passed in the morning. Mr. Adams now urged an operation; and, thinking that any attempts at forcible dilatation, such as Mr. Holt had recommended, would probably fail in consequence of the large size and unusual gristly induration of the stricture, determined to adopt the subcutaneous division of Dr. Dick, more especially as he had assisted Dr. Dick in two operations of this kind in severe cases, in both of which the operation had been eminently successful.

On the 16th of March, 1863, Mr. Adams per-

formed the operation, with the assistance of Dr. Dick. The instruments used were the tenotomy knife, and Dr. Dick's grooved staff with a bulbous extremity, having within it a smaller grooved staff, which can be passed through the stricture, and form a director, along which the knife can be passed in dividing the stricture, when the bulb of the larger staff has been passed down to the stricture as a guide for the introduction of the knife. In performing the operation, the tenotomy knife was passed through the skin externally, directly into the groove in the bulb of the larger staff, and thence onwards along the groove in the smaller staff through the stricture; then, leaving the groove, the knife was directed outwards towards the skin, dividing freely the stricture and some of the corpus spongiosum a little above and below it. In the present case no difficulty occurred in the operation; but, as a complication, two other strictures were discovered by the bulb of the larger staff—one an inch and a half from the external orifice (i. e. nearly an inch anterior to the main stricture), and the other more than an inch behind the main stricture: so that in order to divide these, it was necessary to introduce the tenotomy knife in two different places. When the main stricture was divided, the tissue gave way very much like a tightly-stretched tendon, and could be both heard and felt.

Immediately after the operation, in which very little hæmorrhage occurred, a No. 12 (English) catheter was passed into the bladder without any difficulty, and left in for a short time, slight pressure on the penis being kept up. The catheter was not left in during the night. The next day a No. 12 catheter was introduced twice, and the urine drawn off. This was continued day after day two or three times, and on the fourth day the patient was indiscreet enough to walk down to his club and dine with some friends. Not feeling so well afterwards, he remained two days indoors. On the eighth day he went out of town. He was able to pass a No. 10 catheter for himself without any difficulty, and this he was directed to do at first twice and then once a day. The No. 12 catheter seemed to meet with a little obstruction at the seat of the deepest stricture, or a little beyond this, but passed readily through the situation of the main stricture. On the 15th of April the patient was carefully examined by Mr. Adams, and no disposition to re-contraction existed. He was improved in every respect. On the 8th of June, less than three months from the date of the operation, Mr. Adams reported this gentleman as fit for active military duties. He was now directed to continue passing the No. 10 catheter twice a week and then once a week, which was to be gradually discontinued. It

24 DIVIDING STRICTURES OF THE URETHRA.

may be safely affirmed that in this case no better result could have been obtained by any other method of treatment; and it certainly offers encouragement to test further the advantages of the subcutaneous division of stricture, and determine the cases to which this method of treatment is especially applicable.

ON THE TREATMENT OF STRICTURE

OF THE

URETHRA BY SUBCUTANEOUS DIVISION.

BY

HENRY DICK, B.A., M.D.,

SURGEON TO THE NATIONAL ORTHOPÆDIC HOSPITAL.

READ BEFORE THE ROYAL MEDICAL AND CHIRURGICAL
SOCIETY, JUNE THE 14TH, 1864.

ON THE TREATMENT OF STRICTURE

OF THE

URETHRA BY SUBCUTANEOUS DIVISION.

IN the year 1853 I published, in the *MEDICAL TIMES AND GAZETTE*, a critique on Mr. Syme's operation, in which, for the first time, I related a successful case of subcutaneous section of stricture of the urethra. Subsequently, in the year 1855, I sent a memoir to the Academy of Medicine of France (see Séance, du 23 Octobre, 1855), in which I related two successful cases. Since that time, my friend Mr. William Adams, and my friend and late colleague at the National Orthopædic Hospital, Mr. Allingham, have tried the same method with complete success. In Mr. Adams's case, I had the pleasure of assisting him, and witnessing the successful result of the operation. One of my cases I have lately sent to Mr. Adams that he might see the result of an operation in which he had assisted me more than a year ago; and he is quite convinced that there does not exist the least obstacle or retraction at the place where the stricture existed.

For practical purposes, I divide strictures into two classes : first, those which dilate, or slightly dilate, on the introduction of an instrument ; and, secondly, those which will not dilate at all. In calling them *dilatable* and *undilatable* I only allude to their anatomical and physical properties, not by any means indicating by those terms the nature of their treatment. In a short paper like this, I cannot describe in detail the pathology of stricture ; but, for the object in view, it is sufficient to describe strictures according to their seats : as *single*, when occurring at any spot in the urethra, the most usual part being at the bulb ; or as *double*, or *triple*, the parts most usually affected being the bulb, the membranous portion, and fossa navicularis. But, as I have stated, I have found strictures at other parts of the urethra. Some cases came under my observation where a third or fourth part of the entire urethra was contracted.

Stricture is a result of inflammation ; the normal tissue undergoes an organic change into a tissue of a fibrous nature. The parts constituting the stricture seem to the naked eye atrophied (the most frequent occurrence), but, in rare cases, hypertrophy may take place. By introducing the metallic bougie, we are much assisted in diagnosis as to the existence of atrophy or hypertrophy at

the seat of the stricture. The form of a stricture is like that of two funnels, the points of which touch each other. It is very important to bear in mind this peculiarity in the form of the stricture when cutting is resorted to; because, if the narrowest point only is divided, the patient will not be cured, but symptoms of stricture will return. Another point which is important to advert to, is the direction of the stricture. In parts, obvious to the eye, when long-standing inflammation has taken place, we observe deviation caused by the post-inflammatory contraction; and, according to the same pathological law, deviation is produced in the urethra.

To cure strictures, several methods have been proposed in ancient and modern times. The oldest, and when applied with judgment I believe the safest, is temporary dilatation, and that *by the graduated metallic bougie*; and, according to the pathological particularities which I have already described, it must be obvious that the urethra ought to be subjected to an orthopædic treatment, which can only be effected by a metallic bougie. There are other methods of dilatation, by pouches distended with air or water, which may in particular cases be serviceable; but the metallic bougie is the instrument which gives the most mathematical certitude of the state and improvement of the

strictured parts, and it is by far the most easily managed instrument.

But there are strictures which will not dilate, and the result will be severe complications, as fistula, disease of the bladder, and ureters, and even of the kidneys. In such cases the surgeon is called upon to interfere more energetically. There are sometimes social exigencies which prompt the patient to ask his surgeon to free him radically from his stricture, as when a young man wants to get married, or to go on active service, &c., &c., which would make it very inconvenient for him continually to undergo dilatation.

To produce a breach in the continuity of the strictured parts of the urethra, three methods have been proposed: first, cauterization; second, splitting; and third, cutting: the latter is again subdivided into three methods, viz., internal, external, and subcutaneous.

Keeping in view the pathology of stricture, it is difficult to understand what can be effected by cauterization. There is not too much tissue present; the stricture is not produced by an abnormal superabundance of tissue, but, on the contrary, it is by an atrophy of tissue and contraction that strictures are formed. Every one knows that the physiological action of caustics is just the contrary to that which it should be our object to produce.

Caustics contract parts to which they are applied; a well-known fact in surgery. Moreover, there is great obscurity in using the *potassa fusa* (the caustic most generally used), as we do not know where we cauterize or what we cauterize. I admit there are some cases where the application of nitrate of silver is useful, that is, in highly irritable strictures; in them, the application of lunar caustic makes dilatation possible by allaying the irritability. Consequently, it will be seen that in those cases the caustic can be only regarded as adjuvative.

A second method for radical cure of severe stricture, which has lately come into fashion again, is the violent *splitting* or *tearing* of the contracted parts. Splitting of the urethra originated as far back as thirty years ago, and was practised by Monsieur Mayor, of Lausanne; but his method was found so faulty, that very few surgeons adopted it, and a very warm controversy was carried on between him and the late Monsieur Vidal de Cassis on the subject. Afterwards Mayor's method was improved by Messieurs *Montain*, *Charrière*, *Leroy* (d'Etiolles) *Perréve*, *Civiale*; and in this country by Messrs. Holt and Henry Thomson. The late M. Leroy relates a case of death having taken place within a few hours by this treatment in Berard's practice. (See *Operations, qui se pratiquent*

sur les Organes Genito-Urinaires, par le Docteur Ch. Phillips, page 10). Another case of sudden death through the same operative process is related in the *REVUE MEDICO-CHIRURGICALE*, and in the *ABEILLE MEDICALE* (see 3 *Fevrier*, 1852). I do not know whether any similar accident has occurred in this country, and if any accident should happen it would rather be ascribed to chloroform than to the operation. I mainly look upon the point of the pathological anatomy on which the principle of splitting may be based. It is an old, even in modern times, admitted principle in surgery that retracted parts, if they *can be reached by the knife*, should be *cut* and not *torn*. We only tear parts when we do not exactly know what should be cut, or when the knife cannot safely be used. We admit in surgery to tear down ankylosed joints, when we do not know what elements compose the ankylosis, and we cannot make an exact diagnosis of the fibrous parts composing the ankylosis. On the same principle the method of splitting may be admitted in strictures of the urethra. When there is a long portion of the urethra strictured, or when there are a number of strictures following each other, I think it rational in such cases to have recourse to splitting to effect a radical cure. But even then we labour under the *uncertainty* of—Have we really split the pathologically con-

tracted part, or only forcibly dilated it *without dividing it?*

The third method for the radical cure of severe cases of stricture is to produce a breach of the contracted parts by sharp instruments, and the different proceedings employed to accomplish it may be divided into three methods—First, the *internal*; Secondly, the cutting, *external*, through, not only the strictured parts by a large cut, but all the sound parts covering the stricture. The third method of cutting is the subcutaneous, which makes only a *small* puncture in the sound parts, and with that exception, cuts only the pathologically contracted spots of the urethra.

The internal incision is the most logical, considering the pathological anatomy of strictures, but in the performance of the operation myself and others have found great drawbacks. The instruments invented for such cutting are very ingenious contrivances, but when put to the test they are found to be at fault. The concealed knives are generally too slender to make a deep and long cut, and there is even danger of their breaking. But the most difficult thing in the internal incision is to cause the concealed knife to spring out at the right spot, and if the stricture is not *tensely dilated* the knife acts rather as a dilator than as a *cutting instrument*. Those who have some

practice in cutting fibrous-tissue subcutaneously know how difficult it is to divide it, and it is just that difficulty of cutting the contracted tissue which led me to give up the internal incision. The only indication for the internal incision would be strictures in the fossa navicularis, but even in such cases I have lately preferred to use a director, armed with a dilator, and to cut the stricture by means of a tenotome introduced into the director through the orifice of the urethra.

External incision of the urethra is of old date, and is well known by the name of *la boutonnière*. Mr. Syme has the merit of improving this method, by introducing a director first, and then cutting down on the director; and he has further a very great claim of having largely improved and contributed to a better knowledge of the pathology of strictures. But my objection to the external incision is that it is a formidable operation, almost as hazardous as cutting for stone, and the convalescence is long. There is an idea abroad that if the external incision be not large enough urinary infiltration will take place; but this is an erroneous conception, like that which prevails in respect to cutting for stone, and which has been so very ably exposed by Mr. Henry Thomson. The urine, according to the natural law of gravity, does not burrow under tissues when it has a free channel.

When the stricture is divided the urine follows the course of the urethra, and I shall presently illustrate this dictum by relating the circumstances of a case in my own practice. The healing and suppuration of the open wound is long and tedious, and consequently pyæmia is more likely to occur; parts are divided which have no connection with the existence of the stricture; and through the long suppuration which takes place it is probable that retraction of the divided parts will again take place. Some cases, where this last occurrence happened, I have myself witnessed.

The third method for the radical cure of stricture is the subcutaneous incision practised first by me in this country. The method exactly fulfils all the conditions indicated by the pathological anatomy of strictures; it only punctures to a very small extent the sound parts, which heal up in the first twenty-four hours. It possesses all the advantages of the external incision by leaving the surgeon free to make his cut as long and deep as is necessary. It has further the advantage that there is no occasion to employ chloroform, as the pain caused is very trifling;* the hemorrhage is

* Since the above was written, Dr. Richardson's method of local anæsthesia, which I have often used successfully, has come in to aid the surgeon. The operation described in the text may now be conducted with absolute freedom from pain, and without any delay, by this process.

insignificant, as the surgeon has it in his power only to divide those contracted parts which are not rich in blood-vessels, and leaves the sound part of the urethra intact. The subcutaneous incision is not only indicated in severe cases of stricture, but also in those slighter cases where dilatation might be practised, but where the patient, from his social position, insists on being radically cured in order to avoid the necessity of constantly attending to his stricture.

The method of operating is the following:—Dilatation must, to a small extent, first be accomplished some days previously in order to enable the operator to pass the small grooved conductor through the strictured parts; besides, it has the advantage of accustoming the urethra to the presence of foreign bodies. No chloroform is used. I do not change the patient's regimen. In winter, or bad weather, I take the precaution to let the patient remain for eight days after the operation in doors; not so in summer, and fine weather, when he may go in the open air three days after the operation. If the stricture should be in the membranous portion, an injection will be of use to free the rectum.

The mode of operating is the following:—The patient is placed in the position for lithotomy. The instruments used are a grooved con-

ductor, which I here produce, and an ordinary tenotome, which should have rather a long neck for strictures in the membranous portion. In one case, in which the stricture was in the membranous portion, I found a difficulty in introducing the tenotome into the rectum without doing injury to the bowel or to my finger; for this purpose I propose a tenotome *caché*, in such manner that the sheath may be withdrawn after the knife is introduced in position. A good-sized catheter, in proportion to the orifice of the urethra, and of the same proportion of size should be the conductor. A T shaped bandage, an ordinary bandage, sticking-plaister, and lint are also required. In operating on the membranous portion no bandages are required, and in these cases a large metallic bougie should be left in the urethra to act as a compressor for fear of hemorrhage. The patient once placed in position, I introduce my conducting catheter, which, the Fellows will see has, at its vesical end, two protruding buttons, or knobs, and a groove between them. These protruding buttons are very essential to the operation, as they stop where the stricture begins, but never reach the tightest part, and act at once as a stretcher for the introduced knife. Once in that position, the small-grooved conductor, which is concealed in the large conductor, is by skilful management pushed gently out, and passed

through the stricture. The operator then delivers the conducting catheter into the hands of his assistant, telling him to stretch the penis, and keep the instrument gently but steadily against the stricture. The operator now feels carefully outside of the penis for the buttons of the conducting catheter, where the puncture should be made. Once convinced of the exact locality of the buttons, he grasps with his left hand the penis, together with the instrument, and places his thumb just before the buttons, with his index and middle finger at the back of the penis: grasping those parts surely but gently, he takes now in his right hand the tenotome, thrusts the point between the buttons, and pushes the tenotome resolutely through the stricture. A creaking sensation in cutting the abnormal tissue will be perceived by the operator. I would here remark that the operator should be very careful to make rather a long cut, from three-quarters of an inch to an inch long, and by no means to withdraw his knife until he is quite sure that he has cut through the stricture, and feels through the skin that every obstacle is completely divided. He then removes the knife, withdraws the conductor, and inserts, in proportion to the normal size of the urethra, a large catheter, to *ascertain* if every obstacle is removed. Of course, in introducing

the catheter, the operator must keep the point of the catheter in contact with the upper wall of the urethra, so that the end of the catheter may not drop into the fresh wound. The small external wound should be covered with lint and sticking plaister, with a compress placed over all, and kept in position by a T bandage and common roller formed as a figure of 8, fixed on the hips and wound round the pelvis alternately; the whole is then kept neatly in position by a few pins. The patient afterwards gets into bed and is left quiet. Two or three times a day, when he wants to make water, a large catheter should be introduced to draw off the water and prevent it from coming into contact with the wound of the urethra. I strenuously object to leaving a catheter in the urethra after the operation, on the grounds—1st, because it is greatly to the discomfort of the patient; 2ndly, because it acts in an irritating manner on the bladder itself; and 3rdly, because it will just produce the contrary effect from what it was intended; *i.e.*, the urine will run along the introduced catheter if it be left, and will come into contact with the wound.*

* The instruments used for the subcutaneous division of stricture of the urethra have all been made for me by Mr. G. Ernst, of 19, Calthorpe-street, Gray's-inn-road, W.C.

CASES.

I.

My first operation in the practice of subcutaneous section was performed in the beginning of the year 1853. An Italian gentleman came under my care, with a tight stricture in the membranous portion of the urethra. In this operation I made use of a grooved director having an intra-perineal bend. When the director was in position, with a very small scalpel I made an incision into the membranous portion just lying before the rectum, and of course I was obliged to puncture the rectum also. The scalpel I introduced with difficulty on my finger; and, having made the puncture, I withdrew the scalpel, and left my finger in contact with the puncture: then on my finger I introduced a blunt convex tenotome, and pushing it through the puncture into the grooved director, I divided the stricture. I should not now act in the same manner, as I would prefer to use only one knife in the operation for the membranous portion, namely, a *tenotome caché*. The patient had shi-

vering on the two following days. The urine was withdrawn when required, and never let come in contact with the wound. The patient recovered well. I could pass a large-sized catheter after the operation. I lost sight of this patient, as he left this country some time after the operation.

II.

The next case which came under my care, in the summer of 1854, is the following:—The gentleman came to consult me for gleet in February, 1854. In exploring his urethra, I found a stricture just before the scrotum. I tried several kinds of treatment. Graduated temporary dilatation was for some time used. The stricture yielded, but returned as soon as dilatation was discontinued, and slight gleet never ceased. The gentleman, who was on the point of getting married, was anxious to get rid of his gleet, and was willing to undergo any treatment or operation for the sake of being cured. I proposed to him to divide the stricture, as the only *reasonable* means of ensuring his recovery. He consented, and I divided the stricture subcutaneously; and then for the first time I used my conducting director with the two knobs at the vesical end. I operated on him in

my own consulting-room, and he returned to his lodgings in a cab. In the evening he had shivering; but after some doses of quinine, no more shivering took place. There was a slight swelling in the prepuce and the skin of the scrotum, which after a few days subsided. At the end of eight days he passed his water without a catheter; and after a month there was no trace of stricture or gleet. I have seen this gentleman frequently during the last nine years, and never found the least trace of stricture. About five months ago, for my own instruction, I passed a *bougie à boule*, but could not discover even the seat of the operation.

III.

My third operation I practised in July, 1855. I found in this case a very tight stricture in the fossa navicularis, into which only a very small elastic bougie could be passed. No progress could be made by dilatation. I could not pass a higher number than 20 of Dr. Bennique's gauge. I proposed to the patient to divide his stricture, to which he consented, and I divided the stricture with Dr. Reybard's urethrotome; but, after having divided it, I found another very tight stricture at the bulb. I had not the heart to propose to the

patient another operation at the same time. Afterwards I tried to dilate the second stricture, but made very little progress. This stricture was just as tight as the first. I was convinced that it was necessary to divide it, and proposed to do so in the month of September, 1855. It was divided subcutaneously. There was a remarkable feature in this case, which I think right to mention. After the first operation in the fossa navicularis the patient had no shivering, but after the operation at the bulb shivering took place. However, the patient did well, and has never to this day been troubled with stricture. All my patients are treated for six months, at least, by dilatation, and only the metallic bougie is used temporarily. This last proceeding I look upon as a kind of orthopædic treatment.

IV.

In the year 1856 a patient came under my care with stricture just at the commencement of the bulb. It was very tight, and I tried for a long time to overcome it by dilatation. In the latter end of the year 1861 the patient, during his stay at Dublin, was attacked by retention of urine, no instrument having been passed for some time previously. After suffering for several hours he called in

a surgeon, and was relieved by a bath and a catheter. On his return to London he was anxious to avoid another such occurrence, and I proposed to him to divide his stricture subcutaneously, which operation I performed in January, 1862. Directly after the operation I passed a large catheter, No. 50 of Dr. Bennique's gauge, and drew off the water. The patient was treated according to the rules I have already mentioned. On the evening of the day of the operation, in trying to pass a catheter, I found such a spasmodic contraction in the membranous portion that the patient felt great pain when I reached that spot. To this moment I cannot understand that great degree of spasmodic contraction. It could not be ascribed to a second stricture, because, directly after the operation, I passed a very large catheter. As there was then not much sign of there being urine in the bladder, I left the patient quiet for the night. I was rather uneasy about permitting the patient to make water over the cut wound, fearing urinary infiltration. The next afternoon, not being able to pass any-sized catheter whatever, and finding that each time the foreign body touched the membranous portion the spasm strongly increased, I recommended the patient to make water without any instrument, and, after a little while, he made a large quantity of

water naturally, which caused severe scalding at the cut spot. No bad symptoms whatever followed. He had shivering two days consecutively after the operation, but recovered without the least untoward symptoms, and left his room after eight days' confinement. At the present time there is not the slightest symptom of stricture (1864). In this case Mr. W. Adams assisted me, and fifteen months afterwards, having seen the patient, again has been able to attest to the complete success of the operation.

Mr. Allingham had the kindness to send me the history of two cases, which were operated on by him by the subcutaneous method, and which I shall here give succinctly, with his permission. I must here state that Mr. Allingham was not aware that I had previously operated after the same method. He was consulted by a gentleman from Calcutta who had a long gristly stricture in the spongy portion with a fistulous opening. All known treatment as dilatation, cauterization with *potassa fusa*, and internal incision had been tried and failed, and he came to England to have his stricture cut by external incision. Thinking the subcutaneous incision would be effective in this case, he passed a Brodie's

director through the stricture, and divided it subcutaneously. The patient recovered without any bad symptoms. In eight days the fistulous opening was cured, and he returned to India well, being able to pass a No. 12 catheter easily. This case was operated in June, 1860.

Mr. Allingham's second case was in the year 1862, when a patient came under his care with a long stricture at the beginning of the bulb, and extending higher up into the membranous portion; and in this case also a variety of fruitless treatment preceded the operation. He (Mr. A.) made a puncture into the perineum with a tendon knife, on a grooved staff previously introduced, and divided the first part of the stricture: afterwards he changed his knife for a posterior tibial long-bladed tenotome, and having introduced his finger into the rectum, he felt for the staff; assuring himself, in pushing forwards the knife subcutaneously through the puncture he had previously made, he completely divided the indurated tissue. The case did well, without any untoward symptom but once shivering, and after a month he was discharged cured.

I now draw the following conclusions:—

Firstly. Strictures regarding their physical properties can be divided into dilatable and non-

dilatable, but in both cases a new tissue is formed. In the one it has the property of being dilatable, but will retract again ; in the other no dilatation, or very little, can be effected.

Secondly. Division of the pathologically contracted tissue is the only means of cure.

Thirdly. For division the subcutaneous method is the most proper for easy execution, and for safety of the patient's life.
